Abstract: Self-supported tungsten oxide (WO₃) foams were synthesized by a combination of sol-gel, electrospinning, and thermal oxidation processes. Mixtures of tungsten isopropoxide (C₁₈H₄₂O₆W)-based precursors and cellulose acetate (CA) were electrospun and subsequently heat-treated. Structural characterization of the as-processed foam-like monoliths confirmed that they consist of cubic WO₃ nanoparticles in a continuous matrix with open porosity. The formation of the self-supported nano-foams is a result of self-assembly of the composite nanofibers in the non-woven electrospin mats. The cubic WO₃ foams have a band-gap of 2.53 eV and can be used as visible light photocatalysts.

Keywords: Electrospinning, metal oxide, nano foams, self-supported, photocatalysts.

1. Introduction

Self-supported nanostructures have gained increasing attention recently for use in functional applications instead of dispersed nanoparticles; these include photocatalysis[1, 2], electrochemical energy storage[3], and gas sensing [4]. Among the various self-supported architectures reported, foam structures stand out. Various techniques have been reported to-date to obtain metal oxide foam architectures, including coating of metal foams with metal oxides, polymer-metal oxide composite foams, and pure metal oxide foam structures. The reported techniques for synthesizing pure foams usually require complex processing. For example templating [5, 6] involves filling the mold matrix with metal oxide sol and using calcination or combustion to obtain foams. Thermal treatment of pure metal blocks uses precursors that are typically costly [7]. In this study, a straightforward and cost-effective route to produce metal oxide foams is explored involving the electrospinning process. Tungsten trioxide was chosen as candidate for the study as it finds diverse applications (as visible light photocatalyst, gas sensor, electrochromic material, etc.) and occurs in a variety of polymorphs. Electrospinning of self-supported metal oxide nanofibrous architectures was demonstrated earlier by our group [8-10]. Blend electrospinning involving tungsten isopropoxide (C₁₈H₄₂O₆W) and cellulose acetate, is explored in this work to produce nanostructured foams of WO₃.

2. Experimental Methods:

WO₃ sol was prepared using tungsten isopropoxide (All Chemie Ltd.) as a precursor to blend electrospinning. The sol was prepared with 0.2M concentration in butanol and was subjected to ultrasonic mixing and 48h aging, to allow sufficient time for butoxide substitution. A solution of 0.1M cellulose acetate (CA) (Aldrich 419028) in 40% acetic acid and 60% acetone was prepared; the aged sol was mixed with CA solution in the ratio of 1:4 respectively. The resultant solution was prepared for electrospinning and the resulting as-spun mats were heat treated at 375°C for 8h; the heating and cooling rate were set at 175°C/h.
To study the effect of electrospinning on formation of foam structures, thin films were formed on glass substrate by spin coating. Layer formation on the substrate occurred in 2 cycles. For the first cycle the spin coating parameters were 1000RPM for 9 seconds and for the second cycle the parameters were 200 RPM for 20 seconds. The thickness of the film was controlled by the number of layers deposited on the substrate (1-3). Each layer was completely dried before the next layer was deposited on top. The spin-coated thin films were subjected to the same thermal treatment as the electrospun samples. Scanning Electron microscopy (SEM, LEO 1550) was conducted on the electrospun and spin coated samples. The electrospun samples, obtained upon thermal treatment, were further characterized using transmission electron microscopy (TEM, JEOL 1400), selected area diffraction (SAED), X-ray Diffraction (XRD, Rigaku Miniflex II) and UV-Vis Spectrometer (Jasco J-815).

3. Results

Figure 1 below shows the XRD patterns of the WO3 foams. The peaks obtained come from two phases and were matched to the cubic WO3 (JCPDS 41-905) and a non-stoichiometric oxide of tungsten WO2.9 (JCPDS 18-1417). Formation of cubic WO3 has earlier been reported by our group when annealing the as-spun mats at these temperatures[11]. The formation of non-stoichiometric phase is attributed to an oxygen deficient environment occurring during polymer degradation upon heat-treatment. The relative phase distribution is 60% cubic WO3 and 40% tetragonal WO2.9, based on the relative peak intensities from the XRD pattern.

Figure 2a below shows the Scanning Electron Micrographs for as spun CA-sol-gel nanofibers. Bead formation is seen on the fibers, the formation of beads being the result of a viscous gel formed by the polymer and oxide precursor. Figure 2c shows Scanning Electron Micrographs of the heat-treated samples that further reveal the foam structure. Highly porous foams with a large pore density were obtained by the calcination of the electrospun mats. Typical pore sizes were in the range of 50-70µm.

Figure 3a and 3b show TEM micrographs and SAED patterns for the thermally-threatened material. Highly crystalline WO₃ grains of 20-30nm could be observed inside the foam matrix. A dense distribution of nano sized pores was also observed inside the matrix. The electron diffraction pattern (Fig. 3b) show rings that correspond to the cubic phase of WO₃ (JCPDS #41-905) and match with XRD analysis results.

Optical absorption spectra of the WO₃ foam are shown in Fig. 4a. The light absorption spectrum and the band gap energy of the samples were calculated using the formula \((\alpha h\nu)^2 = A(h\nu-E_g)\). This equation applies to a direct band gap material. \(\alpha\): absorption coefficient, \(h\): Planck constant = 6.63 x 10⁻³⁴ J s, \(\nu\): light frequency, \(E_g\): band gap and \(A\): constant with a value of 1, respectively [12]. The value of the band gap \((E_g)\) is obtained by extrapolating the slope of the \((\alpha h\nu)^2 - h\nu\) plot to where it crosses the x axis (as shown in Fig 4b). Thus, the value of \(E_g\) is estimated to be 2.53 eV for this material. The band gap is the lowest reported for WO₃ nanostructures. The foam, thus, absorbs light with wavelengths in the visible part of the solar spectrum.

Comparison with spin-coated films

Figure 5 shows the SEM images for the spin-coated films. As the number of layers increased, the distribution of particles on the surface of the substrate increased upon heat-treatment. This corresponds to a higher amount of sol being present in the thicker films. Upon thermal treatment and degradation of polymer, the metal oxide film appears to have collapsed and the nanoparticles are now randomly distributed all over the substrate.
Whereas self-supported foams were obtained via the electrospinning process, loose powder networks were seen on the as-spun samples. Figure 6 compares and contrasts the morphologies of (a) foams obtained upon heat treatment of electrospun mats and (b) heat treated thin films.

4. Discussion

The foam structure has likely resulted from the formation of a thick, viscous gel by the sol+CA solution used for electrospinning. The gel formation was the outcome of the interaction of the polymer with metal oxide sol. Such polymer-metal oxide interaction has been reported earlier for hydrated zirconia (HZ)/alumina(HA) with PVP[17]. It was observed that the addition of PVP enhanced the crystallization and dehydration of HZ/HA. The interaction between the PVP and HZ/HA changed during the dehydration process where formation of poly-N-butyl-γ-aminobutyric acid was observed instead. Upon thermal treatment of the mixture at 500°C, pure metal oxides were obtained without any carbon traces.

In this study the polymer-sol gel interactions resulted in a non-homogenous solution. Upon electrospinning beaded fibers were noticed; the formation of beads were partly due to the lack of homogeneity in the solution. Figure 2b is a high magnification image revealing a high concentration of the sol-gel material within the polymer beads. Figure 2a highlights in black polygonal areas of porosity outlined by a high density of beads. The shape and area of these polygons are consistent with the shape and size of the large pores in the foam. Previous work by Schlatter et al. [18] has described the formation of self-assembled honeycomb structures in electrospun polymers. Beads or thicker fibers typically “framed” the walls in these structures.

In the case of CA+sol electrospun mats, when subjected to thermal treatment at 375⁰C, the polymer component melts between 170-240⁰C and breaks down at 370⁰C to water, carbon oxides (CO and CO₂) and methane under an oxidative atmosphere[19]. Upon the polymer decomposition, the sol particles agglomerate to form a dense structure while maintaining a nano structure and nano-sized surface porosity (fig 2d). The macroscopic porosity seen in the foams can be attributed to the honeycomb structures formed during the self-assembly of electrospun mats.

5. Conclusion

We have successfully demonstrated the synthesis of self-supported WO₃ foams via the self-assembly of electrospun fibers. The foams have a band gap of 2.53eV and can be used as visible light photocatalysts.
